Macros and their Impact on Language Design

Shriram Krishnamurthi

2003-11-21

1 Example: For Loops

Many languages provide a looping construct for iterating through integers sequentially. Scheme doesn’t for three reasons:

1. Because most such loops are anyway inappropriate: the indices only exist to traverse sequential data structures. Uses of map or filter over a list accomplish the same thing but at a higher level of abstraction.

2. Because recursion in the presence of tail calls has the same computational effect.

3. Because, if we really crave a more traditional syntax, we can define it using a macro!

We’ll build up a loop macro in three stages.

1.1 Loops with Named Iteration Identifiers

Here’s our first attempt at a for loop macro.¹ We’ve generously embellished it with keywords to increase readability:

```
(define-syntax for0
  (syntax-rules (from to in)
    [(for0 (var) from (low) to (high) in (bodies) ...)
      (local ((define loop (lambda ((var))
           (if (> (var) (high))
                 'done
                 (begin
                   (bodies) ...
                   (loop (+ (var) 1))))))
        (loop (low))))]

This lets us write programs such as

(for0 x
  from 2
to 5
in (display x))

which prints 2, 3, 4 and 5. However, when we try this on a program like this

(for0 x
  from 2
to (read)
in (display x))
```

¹We’re using the convention of wrapping macro pattern-variables in ⟨⋯⟩ to emphasize their relationship to BNF.
we notice an unpleasant phenomenon: the program reads the upper-bound of the loop every time through the loop. To correct it, we should make sure it evaluates the upper-bound expression only once, which we can do with a small change to the macro:

```
(define-syntax for1
  (syntax-rules (from to in)
    [[for1 (var) from (low) to (high) in (bodies) · · ·]
      (local ((define high-value (high))
        (define loop (lambda ((var))
          (if (> (var) high-value)
            'done
            (begin (bodies) · · ·
              (loop (+ (var) 1))))))
        (loop (low)))))])
```

In general, we must be very careful with macros to ensure expressions are evaluated the right number of times. In this instance, (low) is going to be evaluated only once and (var) is only an identifier name, but we have to make sure (high) is evaluated only once.

In fact, however, this version is also buggy! If there is a (read) in the (low) position, that’s going to get evaluated second instead of first, which is presumably not what we wanted (though notice that we didn’t formally specify the behavior of for, either). So to get it right, we really need to evaluate (low) and bind its value to an identifier first.

In general, it’s safer to bind all expression positions to names. Scheme’s eager evaluation semantics ensures the expressions will only be evaluated once. We don’t always want this, but we want it so often that we may as well do it by default. (The times we accidentally bind an expression too early—for instance, the conditional expression of a while loop—we will usually discover the problem pretty quickly by testing.) In addition we must be sure to do this binding in the right order, mirroring what the user expects (and what our documentation for the new language construct specifies). (Notice that the problematic expression in this example is (read), which has the side-effect of prompting the user. Of course, we may want to limit evaluation for efficiency reasons also.)

### 1.2 Loops with Implicit Iteration Identifiers

When we define a loop such as the one above, we often have no real use for the loop variable. It might be convenient to simply introduce an identifier, say it, that is automatically bound to the current value of the loop index. Thus, the first loop example above might instead be written as

```
(for2 from 2
to 5
  in (display it))
```

Here’s a proposed macro that implements this construct:

```
(define-syntax for2
  (syntax-rules (from to in)
    [(for2 from (low) to (high) in (bodies) · · ·)
      (local ((define high-value (high))
        (define loop (lambda (it)
          (if (> it high-value)
            'done
            (begin (bodies) · · ·
              (loop (+ it 1))))))
        (loop (low)))))])
```

Notice that in place of (var), we are now using it. When we run this in DrScheme, we get:

```
> (for2 from 2 to 5 in (display it))
reference to undefined identifier: it
```
Oops! What happened here?

Actually, the macro system did exactly what it should. Remember hygiene? This was supposed to prevent inadvertent capture of identifiers across the macro definition/macro use boundary. It just so happens that in this case, we really do want it written in the macro use to be bound by it in the macro definition. Clearly, here’s a good example of where we want to “break” hygiene, intentionally.

Unfortunately, the simple syntax-rules mechanism we’ve been using so far isn’t quite up to this task; we must instead switch to a slightly more complex macro definition mechanism called syntax-case. For the most part, this looks an awful lot like syntax-rules, with a little more notation. For instance, we can define for3 to be the same macro as for1, except written using the new macro definition mechanism instead:

```
(define-syntax (for3 x)
 (syntax-case x (from to in)
  [(for3 (var) from (low) to (high) in (bodies) · · ·)
   (syntax
    (local ([define high-value (high)])
     [define loop (lambda (var))
      (if (> var high-value)
        'done
        (begin
         (bodies) · · ·
         (loop (+ var 1))))])]
   (loop (low)))]))
```

To convert any syntax-rules macro definition into a corresponding one that uses syntax-case, we must make the three changes boxed above (adding a parameter to the macro name, providing the parameter as an explicit argument to syntax-case, and wrapping the entire output expression in (syntax · · ·)).

We can similarly define for4:

```
(define-syntax (for4 x)
 (syntax-case x (from to in)
  [(for4 from (low) to (high) in (bodies) · · ·)
   (syntax
    (local ([define high-value (high)])
     [define loop (lambda (it))
      (if (> it high-value)
        'done
        (begin
         (bodies) · · ·
         (loop (+ it 1))))])]
   (loop (low)))]))
```

This does not solve the hygiene problem; it simply enables it by converting the macro to use syntax-case. The reason is that syntax-case provides additional capabilities. In particular, it provides a procedure called datum → syntax-object, which takes an arbitrary Scheme datum and a term in the macro body, and “paints” the datum with the same colors as those on the macro body. This has the effect of persuading the hygiene mechanism to treat the introduced term as if it were written by the programmer. As a result, it gets renamed consistently. Thus, we must write

```
(define-syntax (for4 x)
 (syntax-case x (from to in)
  [(for4 from (low) to (high) in (bodies) · · ·)
   (with-syntax ([it (datum → syntax-object (syntax for4) 'it)])
    (syntax
     (local ([define high-value (high)])
      [define loop (lambda (it))
       (if (> it high-value)
         'done
         · · ·)]))]
   (loop (low)))]))
```
The `with-syntax` construct introduces new pattern variables for use in the output. The first argument to `datum→syntax-object` identifies which expression the identifier the expander must pretend “introduced” the identifier. The second, in this case, is the symbol that will be painted appropriately. Therefore, the result of expansion on our running example will look something like

```
(local ([define high-value 5]
           [define loop (lambda (g1729)
                           (if (> g1729 high-value)
                               'done
                               (begin
                                   (display g1729)
                                   (loop (+ g1729 1))))])
           (loop 2))
```

Notice how the uses of `it` are all renamed consistently. (In practice, other bound identifiers such as `high-value` and even `loop` will also acquire fresh names, but we don’t show that here to keep the code more readable.) Indeed, this mechanism is sufficiently robust that it will even do the right thing with nested loops:

```
(for4 from 2 to 5 in
   (for4 from 1 to it in
     (display it))
   (newline))
```

generates

```
1 2
1 2 3
1 2 3 4
1 2 3 4 5
```

In the inner loop, notice that the `it` in the loop bound `(from 1 to it)` is the iteration index for the outer loop, while the `it` in `(display it)` is the index for the inner loop. The macro system associates each `it` appropriately because each use of `for4` gets a different coat of colors. Unfortunately, we have lost the ability to refer to the outer iteration in the inner loop.

### 1.3 Combining the Pieces

A better design for an iteration construct would be to combine these ways of specifying the iteration identifier (explicitly and implicitly). This is easy to do: we simply have two rules.\(^2\) If an identifier is present, use it as before, otherwise bind `it` and recur in the macro.

```
(define-syntax (for5 x)
  (syntax-case x (from to in)
    [(for5 from low to high in bodies · · ·)
     (with-syntax ([it (datum→syntax-object (syntax for5) 'it)])
       (syntax
         (for5 it from low to high in bodies · · ·)))]
    [(for5 var) from low to high in bodies · · ·)
     (syntax
       (local ([define high-value high]
                  [define loop (lambda ((var)))]
         (begin
           (display var)
           (for5 from low to high in bodies · · ·))))])
  )
```

\(^2\)When defining such macros, be very sure to test carefully: if an earlier rule subsumes a later rule, the macro system will not complain, but the code will never get to a later rule! In this case we need not worry since the two rules have truly different structure.
This passes all the expected tests: both the following expressions print the numbers 2 through 5:

\[
\begin{align*}
&\text{(for5 x from 2 to 5 in (display x))} \\
&\text{(for5 from 2 to 5 in (display it))}
\end{align*}
\]

while this

\[
\begin{align*}
&\text{(for5 x from 2 to 5 in} \\
&\quad\text{(for5 from 1 to x in} \\
&\quad\quad\text{(printf "[\~a, \~a] " x it))} \\
&\quad\text{(newline))}
\end{align*}
\]

prints

\[
\begin{align*}
&[2, 1] \ [2, 2] \\
&[3, 1] \ [3, 2] \ [3, 3] \\
&[4, 1] \ [4, 2] \ [4, 3] \ [4, 4] \\
&[5, 1] \ [5, 2] \ [5, 3] \ [5, 4] \ [5, 5]
\end{align*}
\]

There are still ways to many ways of improving this macro. First, we might want to make sure \(<\text{var}>\) is really a variable. We can use \(\text{identifier}\) for this purpose. The \text{syntax-case} mechanism also permits \text{guards}, which are predicates that refine the patterns and don’t allow a rule to fire unless the predicates are met. Finally, the following program does not work:

\[
\begin{align*}
&\text{(for5 x from 2 to 5 in} \\
&\quad\text{(for5 from 1 to [it] in} \\
&\quad\quad\text{(printf "[\~a, \~a] " x it))} \\
&\quad\text{(newline))}
\end{align*}
\]

It reports that the boxed \(\text{it}\) is not bound (why?). Try to improve the macro to bind \(\text{it}\) in this case.

2 Language Design Philosophy

The \(\text{Revised}\) \text{Report on the Algorithmic Language Scheme} famously begins with the following design manifesto:

Programming languages should be designed not by piling feature on top of feature, but by removing the weaknesses and restrictions that make additional features appear necessary.

Scheme augments a minimal set of features with a powerful macro system, which enable the creation of higher-level language primitives. This approach can only work, however, with a carefully designed target language for expansion. Its success in Scheme depends on a potent combination of two forces:

- A set of very powerful core features.
- Very few restrictions on what can appear where (i.e., values in the language are truly \text{first-class}, which in turn means the expressions that generate them can appear nearly anywhere).

The first means many macros can accomplish their tasks with relatively little effort, and the second means the macros can be written in a fairly natural fashion.

This manner of structuring a language means that even simple programs may, unbenownst to the programmer, invoke macros, and tools for Scheme must be sensitive to this fact. For instance, DrScheme is designed to be friendly to beginners. Even simple beginner programs expand into rather complicated and relatively mangled code, many
of whose constructs the beginner will not understand. Therefore, when reporting errors, DrScheme uses various techniques to make sure this complexity is hidden from the programmer.

Building a language through macros does more than just complicate error reporting. It also has significant impact on the forms of generated code that the target implementation must support. Programmers who build these implementations make certain assumptions about the kinds of programs they must handle well; these are invariably based on what “a normal human would write”. Macros, however, breaks these unwritten rules. They produce unusual and unexpected code, resulting in correctness and, particularly, performance errors. Sometimes these are easy to fix; in many other cases they are not. We will study examples to illustrate instances where macros crucially depend on the target language’s handling of certain key code patterns.

3 Example: Pattern Matching

We will now examine a rather unusual construct that a programmer would never write, and explain why an implementation should nevertheless search for instances of it and handle it efficiently. To set the stage, consider the Scheme construct \( \text{let} \), which binds names to values in a local lexical context. Though this (or an equivalent way of introducing local scope) would be a language primitive in most languages, in Scheme this is expressible as a rather simple macro in terms of first-class functions. That is,

\[
\text{let } ((v \ e \ \cdots) \ b)
\]

can be implemented by expanding into\(^3\)

\[
(\lambda (v \ e \ \cdots) \ b) \ e \ \cdots
\]

where \((\lambda (v \ e \ \cdots) \ b)\) introduces an (anonymous) procedure with argument list \(v \ \cdots\) and body \(b\), and the outer parentheses apply this procedure to the argument expressions \(e \ \cdots\). The application binds the variables \(v \ \cdots\) to the values of the expressions \(e \ \cdots\), and in that extended environment evaluates the body \(b\)---exactly what we would intend as the semantics for \text{let}. For instance, the program

\[
(\text{let } [(x 3)]
[y 2])
(+ x y))
\]

which evaluates to 2 + 3, i.e., 5, is transformed into

\[
(\lambda (x \ y) (+ x y))
3 2)
\]

This macro is, in fact, quite easy to implement: thanks to hygiene and pattern matching, the implementer of \text{let} merely needs to write

\[
\text{(define-syntax let}
\text{(syntax-rules ()}
  [(let ((v e) \cdots) b) \text{(lambda (v e) \cdots) b})]
\text{)}
\]

The Scheme pre-processor finds all bodies of the form \((\text{let} \ \cdots)\), matches them against the input pattern (here, \((\text{let} \ ((v \ e) \ \cdots) \ b)\)), binds the pattern variables \((v \ e \text{ and } b)\) to the corresponding sub-expressions, and replaces the body with the output pattern in which the pattern variables have been replaced by the sub-expressions bound to them.

There is, however, a significant performance difference between the two forms. A compiler can implement \text{let} by extending the current activation record with one more binding (for which space can be pre-allocated by the creator of the record). In contrast, the expanded code forces the compiler to both create a new closure and then apply it---both relatively more expensive operations.

Given this expense, you might think it silly for a Scheme system to implement the \text{let-to-lambda} macro: why take an efficient source-language instruction, whose intent is apparent, and make it less efficient behind the programmer’s

---

\(^3\)For simplicity, we assume the body has only one expression. In reality, Scheme permits multiple expressions in the body, which is useful in imperative programs.
back? Yet at least one Scheme compiler (Chez Scheme) does precisely this. Furthermore, in the back end, it finds instances of ((lambda ...)) and effectively handles them as it would have let.

Why would a compiler behave so perversely? Surely no human would intentionally write ((lambda ...)), so how else could these arise? The operative phrase is, of course, “no human”. Scheme programs are full of program-generating programs, and by treating this odd syntactic pattern as a primitive, all macros that resolve into it benefit from the compiler’s optimizations.

Consider a simple symbol-based conditional matcher: the user writes a series of symbol and action pairs, such as

\[
\text{(switch [off 0] [on 1])}
\]

The matcher performs the symbol comparison and, when a symbol matches, executes the corresponding action (in this case, the actions are already numerical values). The entire (switch ...) expression becomes a function of one argument, which is the datum to compare. Thus, a full program might be

\[
\text{(define m (switch [off 0] [on 1]))}
\]

with the following interactions with the Scheme evaluator:

\[
> (m \text{'off})
\]

\[
0
\]

\[
> (m \text{'on})
\]

\[
1
\]

To implement switch, we need a macro rule when there are one or more cases:

\[
\text{(switch} \text{⇒ (lambda (v)} \text{if (symbol=? v (quote sym0)) act0 ((switch [pat-rest act-rest] \text{...}) v))}
\]

This yields a function that consumes the actual value (v) to match against. The matcher compares v against the first symbol. If the comparison is successful, it invokes the first action. Otherwise it needs to invoke the pattern-matcher on the remaining clauses. Since a matcher is a function, invoking it is a matter of function application. So applying this function to v will continue the matching process.\(^4\)

For completeness, we also need a rule when no patterns remain. For simplicity, we define our matcher to return false\(^5\) (a better response might be to raise an exception):

\[
\text{(switch} \text{⇒ (lambda (v) false)}
\]

Combining these two rules gives us the complete macro, shown in Fig. 1.

Given this macro, the simple use of switch given above generates

\[
\text{(lambda (v0)} \text{if (symbol=? v0 (quote off)) 0 ((lambda (v1)} \text{if (symbol=? v1 (quote on)) 1 ((lambda (v2)}}
\]

\(^4\)The ... denotes “zero or more”, so the pattern of using one rule followed by a ... is common in Scheme macros to capture the potential for an unlimited number of body expressions.

\(^5\)In many Scheme systems, true and false are written as #t and #f, respectively.
(define-syntax switch
  (syntax-rules ()
    [(switch) (lambda (v) false)]
    [(switch [sym0 act0]
      [pat-rest act-rest]...
    )
      (lambda (v)
        (if (symbol=? v (quote sym0))
          act0
          ((switch [pat-rest act-rest]...
            v))))]))

Figure 1: Simple Pattern Matcher

(I’ve used different names for each v, as the hygienic expander might, to make it easy to keep them all apart. Each v is introduced by another application of the switch macro.)

While this expanded code is easy to generate, its performance is likely to be terrible: every time one clause fails to match, the matcher creates and applies another closure. As a result, even if the programmer wrote a pattern matching sequence that contained no memory-allocating code, the code might yet allocate memory! That would be most unwelcome behavior.

Fortunately, the compiler comes to the rescue. It immediately notices the ((lambda · · · · ·)) pattern and collapses these, producing effectively the code:

(lambda (v0)
  (if (symbol=? v0 (quote off))
    0
    (let ([v1 v0])
      (if (symbol=? v1 (quote on))
        1
        (let ([v2 v1])
          false)))))

In fact, since the compiler can now see that these lets are now redundant (all they do is rename a variable), it can remove them, resulting in this code:

(lambda (v0)
  (if (symbol=? v0 (quote off))
    0
    (if (symbol=? v0 (quote on))
      1
      false)))

This is pretty much exactly what you would have been tempted to write by hand. In fact, read it and it’s obvious that it implements a simple conditional matcher over symbols. Furthermore, it has a very convenient interface: a matcher is a first-class function value suitable for application in several contexts, being passed to other procedures, etc. The macro produced this by recursively generating lots of functions, but a smart choice of compiler “primitive”—((lambda · · · · ·)), in this case—that was sensitive to the needs of macros reduced the result to taut code. Indeed, it now leaves the code in a state where the compiler can potentially apply further optimizations (e.g., for large numbers of comparisons, it can convert the cascade of comparisons into direct branches driven by hashing on the symbol being compared).
4 Example: Automata

Next, we examine another optimization that is crucial for capturing the intended behavior of many programs. As an example, suppose we want to define automata manually. Ideally, we should be able to specify the automata once and have different interpretations for the same specification; we also want the automata to be as easy as possible to write (here, we stick to textual notations). In addition, we want the automata to execute fairly quickly, and to integrate well with the rest of the code (so they can, for instance, be written in-line in programs).

Concretely, suppose we want to write a simple automaton that accepts only patterns of the form \((01)^*\). We might want to write this textually as

\[
\text{automaton see0}
\]
\[
\text{see0 : 0 -> see1}
\]
\[
\text{see1 : 1 -> see0}
\]

where the state named after the keyword \texttt{automaton} identifies the initial state.

Consider a slightly more complex automaton, one that recognizes the Lisp identifier family \texttt{car}, \texttt{cdr}, \texttt{cadr}, \texttt{cddr}, \texttt{cddar} and so on. That is, it should recognize the language \(c(ad)^*r\). Its automaton might look like

\[
\text{automaton init}
\]
\[
\text{init : c -> more}
\]
\[
\text{more : a -> more}
\]
\[
\text{d -> more}
\]
\[
\text{r -> end}
\]

end :

We leave defining a more formal semantics for the automaton language as an exercise for the reader.

It is easy to see that some representation of the textual description suffices for treating the automata statically. How do we implement them as programs with dynamic behavior? \textit{We request you, dear reader, to pause now and sketch the details of an implementation before proceeding further.}

A natural implementation of this language is to create a vector or other random-access data structure to represent the states. Each state has an association indicating the actions—implemented as an association list, associative hash table, or other appropriate data structure. The association binds inputs to next states, which are references or indices into the data structure representing states. Given an actual input stream, a program would walk this structure based on the input. If the stream ends, it would accept the input; if no next state is found, it would reject the input; otherwise, it would proceed as per the contents of the data structure. (Of course, other implementations of acceptance and rejection are possible.)

One Scheme implementation of this program would look like this. First we represent the automaton as a data structure:

\[
\text{(define machine '((init (c more)) (more (a more) (d more) (r end)) (end)))}
\]

The following program is parameterized over machines and inputs:

\[
\text{(define (run machine init-state stream))}
\]
\[
\text{(define (walker state stream))}
\]
\[
\text{(or (empty? stream) ;; if empty, return true, otherwise ...}
\]
\[
\text{(let ((transitions (cdr (assv state machine)))}
\]
\[
\text{[in (first stream)])}}
\]
\[
\text{(let ((new-state (assv in transitions)))}
\]
\[
\text{(if new-state}
\]
\[
\text{(walker (cdr new-state) (rest stream))}
\]
\[
\text{false)))))}
\]
\[
\text{(walker init-state stream))}
\]
Here are two instances of running this:

```
> (run machine 'init '(c a d a d d r))
true
> (run machine 'init '(c a d a d d r))
false
```

This is not the most efficient implementation we could construct in Scheme, but it is representative of the general idea.

While this is a correct implementation of the semantics, it takes quite a lot of effort to get right. It’s easy to make mistakes while querying the data structure, and we have to make several data structure decisions in the implementation (which we have done only poorly above). Can we do better?

To answer this question affirmatively, let’s ignore the details of data structures and understand the essence of these implementations.

1. Per state, we need fast conditional dispatch to determine the next state.
2. Each state should be quickly accessible.
3. State transition should have low overhead.

Let’s examine these criteria more closely to see whether we can recast them slightly:

**Fast conditional dispatch** This could just be a conditional statement in a programming language. Compiler writers have developed numerous techniques for optimizing properly exposed conditionals.

**Rapid state access** Pointers of any sort, including pointers to functions, would offer this.

**Quick state transition** If only function calls were implemented as gotos…

In other words, the `init` state could be represented by

```
(lambda (stream)
  (or (empty? stream)
      (case (first stream)
        [(c) (more (rest stream))]
        [else false])))
```

That is, if the stream is empty, the procedure halts returning a true value; otherwise it dispatches on the first stream element. Note that the boxed expression is invoking the code corresponding to the `more` state. The code for the `more` state would similarly be

```
(lambda (stream)
  (or (empty? stream)
      (case (first stream)
        [(a) (more (rest stream))]
        [(d) (more (rest stream))]
        [(r) (end (rest stream))]
        [else false])))
```

Each underlined name is a reference to a state: there are two self-references and one to the code for the `end` state. Finally, the code for the `end` state fails to accept the input if there are any characters in it at all. While there are many ways of writing this, to remain consistent with the code for the other states, we write it as

```
(lambda (stream)
  (or (empty? stream)
      (case (first stream) ;; no matching clauses, so always false
        [else false])))
```
The full program is shown in Fig. 2. This entire definition corresponds to the machine; the definition of 
\texttt{machine} is bound to \texttt{init}, which is the function corresponding to the \texttt{init} state, so the resulting value needs only be applied to the input stream. For instance:

\begin{verbatim}
> (machine '(c a d a d d r))
true
> (machine '(c a d a d d r r))
false
\end{verbatim}

What we have done is actually somewhat subtle. We can view the first implementation as an \textit{interpreter} for the language of automata. This moniker is justified because that implementation has these properties:

\begin{enumerate}
\item Its output is an answer (whether or not the automaton recognizes the input), not another program.
\item It has to traverse the program’s source as a data structure (in this case, the description of the automaton) repeatedly across inputs.
\item It consumes both the program and a specific input.
\end{enumerate}

It is, in fact, a very classical interpreter. Modifying it to convert the automaton data structure into some intermediate representation would eliminate the second overhead in the second clause, but would still leave open the other criteria.

In contrast, the second implementation given above is the \textit{result of compilation}, i.e., it is what a compiler from the automaton language to Scheme might produce. Not only is the result a program, rather than an answer for a certain input, it also completes the process of transforming the original representation into one that does not need repeated processing.

While this compiled representation certainly satisfies the automaton language’s semantics, it leaves two major issues unresolved: efficiency and conciseness. The first owes to the overhead of the function applications. The second is evident because our description has become much longer; the interpreted solution required the user to provide only a concise description of the automaton, and reused a generic interpreter to manipulate that description. What is missing here is the actual compiler that can generate the compiled version.

---

\begin{verbatim}
(define machine
(letrec ((init
  (lambda (stream)
    (or (empty? stream)
      (case (first stream)
        [(c) (more (rest stream))]
        [else false])))))

[more
  (lambda (stream)
    (or (empty? stream)
      (case (first stream)
        [(a) (more (rest stream))]
        [(d) (more (rest stream))]
        [(t) (end (rest stream))]
        [else false]))))

[end
  (lambda (stream)
    (or (empty? stream)
      (case (first stream)
        [else false]))))

init))
\end{verbatim}
Figure 3: A Macro for Executable Automata

4.1 Concision

First, let us slightly alter the form of the input. We assume that automata are written using the following syntax (presented informally):

\( \text{automaton} \text{init} \)
\( \text{init} : (c \rightarrow \text{more}) \)
\( \text{more} : (a \rightarrow \text{more}) \)
\( (d \rightarrow \text{more}) \)
\( (r \rightarrow \text{end}) \)
\( (\text{end} : ) \)

The general transformation we want to implement is quite clear from the result of compilation, above:

\( (\text{state} : (\text{label} \rightarrow \text{target}) \cdots) \Rightarrow (\text{lambda} \text{stream}) \)
\( (\text{or} (\text{empty} \text{? stream}) \)
\( (\text{case} (\text{first stream}) \)
\( (\text{[label]} (\text{target} (\text{rest stream}))) \)
\( \cdots \)
\( [\text{else false}]))) \)

Having handled individual rules, we must make the automaton macro wrap all these procedures into a collection of mutually-recursive procedures. The result is the macro shown in Fig. 3. To use the automata that result from instances of this macro, we simply apply them to the input:

\( > \text{(define m (automaton init} \)
\( \text{[init : (c \rightarrow more)]} \)
\( \text{[more : (a \rightarrow more)} \)
\( \text{(d \rightarrow more)} \)
\( \text{(r \rightarrow end)} \)
\( \text{[end : ]}) \)
\( > (m \text{'(c a d a d d r})) \)
\( \text{true} \)
\( > (m \text{'(c a d a d d r r))} \)
\( \text{false} \)

By defining this as a macro, we have made it possible to truly embed automata into Scheme programs. This is true purely at a syntactic level—since the Scheme macro system respects the lexical structure of Scheme, it does not
face problems that an external syntactic preprocessor might face. In addition, an automaton is just another applicable Scheme value. By virtue of being first-class, it becomes just another linguistic element in Scheme, and can participate in all sorts of programming patterns.

In other words, the macro system provides a convenient way of writing compilers from “Scheme+” to Scheme. More powerful Scheme macro systems allow the programmer to embed languages that are truly different from Scheme, not merely extensions of it, into Scheme. A useful slogan (due to Matthew Flatt and quite possibly others) for Scheme’s macro system is that it’s a lightweight compiler API.

4.2 Efficiency

The remaining complaint against this implementation is that the cost of a function call adds so much overhead to the implementation that it negates any benefits the automaton macro might conceivably manifest. In fact, that’s not what happens here at all, and this section examines why not.

Tony Hoare once famously said, “Pointers are like jumps”\(^6\). What we are seeking here is the reverse of this phenomenon: what is the goto-like construct that corresponds to a dereference in a data structure? The answer was given by Guy Steele: the tail call.

Armed with this insight, we can now reexamine the code. Studying the output of compilation, or the macro, we notice that the conditional dispatcher invokes the function corresponding to the next state on the rest of the stream—but does not touch the return value. This is no accident: the macro has been carefully written to only make tail calls.\(^7\)

In other words, the state transition is hardly more complicated than finding the next state (which is statically determinate, since the compiler knows the location of all the local functions) and executing the code that resides there. Indeed, the code generated from this Scheme source looks an awful lot like the automaton representation we discussed at the beginning of section 4: random access for the procedures, references for state transformation, and some appropriately efficient implementation of the conditional.

The moral of this story is that we get the same representation we would have had to carefully craft by hand virtually for free from the compiler. In other words, languages represent the ultimate form of reuse, because we get to reuse everything from the mathematical (semantics) to the practical (libraries), as well as decades of research and toil in compiler construction.

Tail Calls versus Tail Recursion

This example should help demonstrate the often-confused difference between tail calls and tail recursion. Many books discuss tail recursion, which is a special case where a function makes tail calls to itself. They point out that, because implementations must optimize these calls, using recursion to encode a loop results in an implementation that is really no less efficient than using a looping construct. They use this to justify, in terms of efficiency, the use of recursion for looping.

These descriptions unfortunately tell only half the story. While their comments on using recursion for looping are true, they obscure the subtlety and importance of optimizing all tail calls, which permit a family of functions to invoke one another without experiencing penalty. This leaves programmers free to write readable programs without paying a performance penalty—a rare “sweet spot” in the readability-performance trade-off. Traditional languages that offer only looping constructs and no tail calls force programmers to artificially combine procedures, or pay via performance.

The functions generated by the automaton macro are a good illustration of this. If the implementation did not perform tail-call optimization but the programmer needed that level of performance, the macro would be forced to somehow combine all the three functions into a single one that could then employ a looping construct. This leads to an unnatural mangling of code, making the macro much harder to develop and maintain.

5 Other Uses

Scheme macros can do many more things. datum—syntax-object can be used to manufacture identifiers from syntax supplied to the macro. Macros can also define other macros! You might find such examples as you begin to employ

---

\(^6\)The context for the quote is pejorative: “Pointers are like jumps, leading wildly from one part of the data structure to another. Their introduction into high-level languages has been a step backwards from which we may never recover.”

\(^7\)Even if the code did need to perform some operation with the result, it is often easy in practice to convert the calls to tail-calls using accumulators. In general, as we have seen, the conversion to continuation-passing style converts all calls to tail calls.
You might find Kent Dybvig’s *The Scheme Programming Language* and Paul Graham’s *On Lisp* useful books to understand these paradigms better.

## 6 Perspective

We have now seen several examples of Scheme’s macro system at work. In the process, we have seen how features that would otherwise seem orthogonal, such as macros, first-class procedures and tail-calls, are in fact intimately wedded together; in particular, the absence of the latter two would greatly complicate use of the former. In this sense, the language’s design represents a particularly subtle, maximal point in the design space of languages: removing any feature would greatly compromise what’s left, while what is present is an especially good notation for describing algorithms.
