CS 33

Libraries
Libraries

- Collections of useful stuff
- Allow you to:
  - incorporate items into your program
  - substitute new stuff for existing items
- Often ugly …
Files ending with “.a” are known as *archives* or *static libraries*. 
The routine “puts” is from the standard-I/O library, just as printf is, but it’s far simpler. It prints its single string argument, appending a ‘\n’ (newline) to the end.

Note that “-lpriv1” (the second character of the string is a lower-case L and the last character is the numeral one) is, in this example, shorthand for libpriv1.a, but we’ll soon see that it’s shorthand for more than that.

Normally, libraries are expected to be found in the current directory. The “-L” flag is used to specify additional directories in which to look for libraries.
Static-Linking: What’s in the Executable

- **ld puts in the executable:**
  - (assuming all `.c` files have been compiled into `.o` files)
  - all `.o` files from argument list (including those newly compiled)
  - `.o` files from archives as needed to satisfy unresolved references
    - some may have their own unresolved references that may need to be resolved from additional `.o` files from archives
    - each archive processed just once (as ordered in argument list)
      - order matters!
Example

```
$ cat prog2.c
int main() {
    void func1();
    func1();
    return 0;
}

$ cat func1.c
void func1() {
    void func2();
    func2();
}

$ cat func2.c
void func2() {
}
```
Order Matters ...

$ ar t libf1.a
  func1.o
$ ar t libf2.a
  func2.o
$ gcc -o prog2 prog2.c -L -lf1 -lf2
  $
$ gcc -o prog2 prog2.c -L -lf2 -lf1
  ./libf1.a(sub1.o): In function `func1':
  func1.c:(.text+0xa): undefined reference to `func2'
  collect2: error: ld returned 1 exit status
Substitution

$ cat myputs.c

int puts(char *s) {
    write(1, "My puts: ", 9);
    write(1, s, strlen(s));
    write(1, "\n", 1);
    return 1;
}

$ gcc -c myputs.c
$ ar cr libmyputs.a myputs.o
$ gcc -o prog prog.c -L. -lpriv1 -lmyputs
$ ./prog
My puts: sub1
My puts: sub2
My puts: sub3
An Urgent Problem

- printf is found to have a bug
  - perhaps a security problem
- All existing instances must be replaced
  - there are zillions of instances ...
- Do we have to re-link all programs that use printf?
Dynamic Linking

- Executable is not fully linked
  - contains list of needed libraries
- Linkages set up when executable is run
Benefits

• Without dynamic linking
  – every executable contains copy of printf (and other stuff)
    » waste of disk space
    » waste of primary memory

• With dynamic linking
  – just one copy of printf
    » shared by all
Linux supports two kinds of libraries — static libraries, contained in *archives*, whose names end with “.a” (e.g. *libc.a*) and *shared* objects, whose names end with “.so” (e.g. *libc.so*). When *ld* is invoked to handle the linking of object code, it is normally given a list of libraries in which to find unresolved references. If it resolves a reference within a *.a* file, it copies the code from the file and statically links it into the object code. However, if it resolves the reference within a *.so* file, it records the name of the shared object (not the complete path, just the final component) and postpones actual linking until the program is executed.

If the program is fully bound and relocated, then it is ready for direct execution. However, if it is not fully bound and relocated, then *ld* arranges things so that when the program is executed, rather than starting with the program’s main routine, a runtime version of *ld*, called *ld-linux.so*, is called first. *ld-linux.so* maps all the required libraries into the address space and then calls the main routine.
Creating a Shared Library (1)

$ gcc -fPIC -c myputs.c
$ ld -shared -o libmyputs.so myputs.o
$ gcc -o prog prog.c -L. -lprivil -lmyputs
$ ./prog
./prog: error while loading shared libraries: libmyputs.so: cannot open shared object file: No such file or directory
$ ldd prog
linux-vdso.so.1 => (0x00007fff953fc000)
libmyputs.so => not found
libc.so.6 => /lib/x86_64-linux-gnu/libc.so.6 (0x00007f7389174000)
/lib64/ld-linux-x86-64.so.2 (0x00007f7389536000)

The –fPIC flag tells gcc to produce “position-independent code,” which is something we discuss soon. The ld command invokes the loader directly. The –shared flag tells it to created a shared object. In this case, it’s creating it from the object file myputs.o and calling the shared object libmyputs.so.

The error occurs because we haven’t indicated in the executable (prog) where ld-linux.so should look for shared objects. The ldd (list dynamic dependencies) command, which looks at all the shared objects referenced in the executable and prints out where they are found, shows us what the problem is.
$ gcc -o prog prog.c -fPIC -L. -lprivl -lmyputs -Wl,-rpath \
/home/twd/libs
$ ldd prog
linux-vdso.so.1 => (0x00007fff235ff000)
libmyputs.so => /home/twd/libs/libmyputs.so (0x00007f821370f000)
libc.so.6 => /lib/x86_64-linux-gnu/libc.so.6 (0x00007f821314e000)
/lib64/ld-linux-x86-64.so.2 (0x00007f8213912000)
$ ./prog
My puts: sub1
My puts: sub2
My puts: sub3

The “-Wl,-rpath /home/twd/libs” flag (the third character of the string is a lower-case L) tells the loader to indicate in the executable (prog) that ld-linux.so should look in the indicated directory for shared objects. (The “-Wl” part of the flag tells gcc to pass the rest of the flag to the loader.)
Order Still Matters

- All shared objects listed in the executable are loaded into the address space
  - whether needed or not
- ldd-linux.so will find anything that’s there
  - looks in the order in which shared objects are listed
A Problem

- You've put together a library of useful functions
  - libgoodstuff.so
- Lots of people are using it
- It occurs to you that you can make it even better by adding an extra argument to a few of the functions
  - doing so will break all programs that currently use these functions
- You need a means so that old code will continue to use the old version, but new code will use the new version
A Solution

- The two versions of your program coexist
  - libgoodstuff.so.1
  - libgoodstuff.so.2
- You arrange so that old code uses the old version, new code uses the new
- Most users of your code don't really want to have to care about version numbers
  - they want always to link with libgoodstuff.so
  - and get the version that was current when they wrote their programs
Here we are creating two versions of libgoodstuff, in libgoodstuff.so.1 and in libgoodstuff.so.2. Each is created by invoking the loader directly via the “ld” command. The “-soname” flag tells the loader to include in the shared object its name, which is the string following the flag (“libgoodstuff.so.1” in the first call to ld). The effect of the “ln –s” command is to create a new name (its last argument) in the file system that refers to the same file as that referred to by ln’s next-to-last argument. Thus, after the first call to ln –s, libgoodstuff.so refers to the same file as does libgoodstuff.so.1. Thus the second invocation of gcc, where it refers to –lgoodstuff (which expands to libgoodstuff.so), is actually referring to libgoodstuff.so.1.

Then we create a new version of goodstuff and from it a new shared object called libgoodstuff.so.2 (i.e., version 2). The call to “rm” removes the name libgoodstuff.so (but not the file it refers to, which is still referred to by libgoodstuff.so.1). Then ln is called again to make libgoodstuff.so now refer to the same file as does libgoodstuff.so.2. Thus when prog2 is linked, the reference to –lgoodstuff expands to libgoodstuff.so, which now refers to the same file as does libgoodstuff.so.2.

If prog1 is now run, it refers to libgoodstuff.so.1, so it gets the old version (version 1), but if prog2 is run, it refers to libgoodstuff.so.2, so it gets the new version (version 2). Thus programs using both versions of goodstuff can coexist.
Interpositioning

prog

wrapper

puts
__wrap_puts is the “wrapper” for puts. __real_puts is the “real” puts routine. What we want is for calls to puts to go to __wrap_puts, and calls to __real_puts to go to the real puts routine (in stdio).
The arguments to gcc shown in the slide cause what we asked for in the previous slide to actually happen. Calls to `puts` go to `__wrap_puts`, and calls to `__real_puts` go to the real `puts` routine.
An alternative approach to wrapping is to invoke ld-linux.so directly from the program, and have it find the real puts routine. The call to dlsym above directly invokes ld-linux.so, asking it (as given by the first argument) to find the next definition of puts in the list of libraries. It returns the location of that routine, which is then called (*pptr).
What’s Going On …

- gcc/ld
  - compiles code
  - does static linking
    » searches list of libraries
    » adds references to shared objects
- runtime
  - program invokes `ld-linux.so` to finish linking
    » maps in shared objects
    » does relocation and procedure linking as required
  - `dlsym` invokes `ld-linux.so` to do more linking
    » RTLD_NEXT says to use the next (second) occurrence of the symbol
Delayed Wrapping

- **LD_PRELOAD**
  - environment variable checked by *ld-linux.so*
  - specifies additional shared objects to search (first) when program is started
Environment Variables

- Another form of exec
  - `int execve(const char *filename, char *const argv[], char *const envp[]);`

- `envp` is an array of strings, of the form
  - `key=value`

- Programs can search for values, given a key

- Example
  - `PATH=~/bin:/bin:/usr/bin:/course/cs0330/bin`
Here we add “LD_PRELOAD=./libmputs.so.1” to the environment. The export command instructs the shell to supply this as part of the environment for the commands it runs.

Problem

• How is relocation handled?
Assuming we’re using pre-relocation, the C library and the math library would be assumed to be in virtual memory at their pre-assigned locations. In the slide, these would be starting at locations 1,000,000 and 3,000,000, respectively. Let’s suppose printf, which is in the C library, is at location 1,000,400. Thus calls to printf at static link time could be linked to that address. If the math library also contains calls to printf, these would be linked to that address as well. The C library might contain a global identifies, such as stdfiles. Its address would also be known.
Pre-relocation doesn’t work if we have two libraries pre-assigned such that they overlap. If so, at least one of the two will have to be moved, necessitating relocation.
But ...
Quiz 1

We need to relocate all references to Mary’s library in my library. What option should we give to `mmap` when we map mylibrary into our address space?

a) the MAP_SHARED option
b) the MAP_PRIVATE option
c) mmap can’t be used in this situation
Relocation Revisited

- Modify shared code to effect relocation
  - result is no longer shared!
- Separate shared code from (unshared) addresses
  - position-independent code (PIC)
  - code can be placed anywhere
  - addresses in separate private section
    » pointed to by a register
The C library (and other libraries) can be mapped into different locations in different processes' address spaces.
For this slide, we assume relocation is dealt with through the use of position-independent code (PIC).

To provide position-independent code on x86-64, ELF requires three data structures for each dynamic executable (i.e., the program binary loaded by `exec`) and shared object: the *procedure-linkage table*, the *global-offset table*, and the *relocation table*. To simplify discussion, we refer to dynamic executables and shared objects as *modules*. The procedure linkage table contains the code that’s actually called when control is to be transferred to an externally defined routine. It is shared by all processes using the associated executable or object, and makes use of data in the global-object table to link the caller to the called program. Each process has its own private copy of each global-object table. It contains the relocated addresses of all externally defined symbols. Finally, the relocation table contains much information about each module. What is used for linking is relocation information and the symbol table, as we explain in the next few slides.

How things work is similar for other architectures, but definitely not the same.
To establish position-independent references to global variables, the compiler produces, for each module, a *global-offset table*. Modules refer to global variables indirectly by looking up their addresses in the table, using PC-relative addressing. The item needed is at some fixed offset from the beginning of the table. When the module is loaded into memory, ld-linux.so is responsible for putting into it the actual addresses of all the needed global variables.
Procedures in Shared Objects

- Lots of them
- Many are never used
- Fix up linkages on demand
An Example

```c
int main( ) {
    puts("Hello world\n");
    ...
    return 0;
}
```

000000000000006b0 <main>:
6b0: 55                  push %rbp
6b1: 48 89 e5            mov %rsp,%rbp
6b4: 48 8d 3d 99 00 00 00 lea 0x99(%rip),%rdi
6bb: e8 a0 fe ff ff      callq 560 <puts@plt>
...

The top half of the slide contains an excerpt from a C program. For the bottom half, we’ve compiled the program and have printed what "objdump -d" produces for main. Note that the call to puts is actually a call to "puts@plt", which is a reference to the procedure linkage table.
Dealing with references to external procedures is considerably more complicated than dealing with references to external data. This slide shows the procedure linkage table, global offset table, and relocation information for a module that contains references to external procedures `puts` and `name2`. Let’s follow a call to procedure `puts`. The general idea is before the first call to puts, the actual address of the puts procedure is not recorded in the global-offset table, Instead, the first call to puts actually invokes `ld-linux.so`, which is passed parameters indicating what is really wanted. It then finds puts and updates the global-offset table so that things are more direct on subsequent calls.

To make this happen, references from the module to `puts` are statically linked to entry `.puts` in the procedure-linkage table. This entry contains an unconditional jump (via PC-relative addressing) to the address contained in the `puts` offset of the global-offset table. Initially this address is of the instruction following the jump instruction, which contains code that pushes onto the stack the offset of the `puts` entry in the relocation table. The next instruction is an unconditional jump to the beginning of the procedure-linkage table, entry `.PLT0`. Here there’s code that pushes onto the stack the second 64-bit word of the global-offset table, which contains a value identifying this module. The following instruction is an unconditional jump to the address in the third word of the global-offset table, which is conveniently the address of `ld-linux.so`. Thus control finally passes to `ld-linux.so`, which looks back on the stack and determines which module has called it and what that module really wants to call. It figures this out based on the module-identification word and the relocation table entry, which contains the offset of the `puts` entry in the global-offset table (which is what must be updated) and the index of `puts` in the symbol table (so it knows the name of what it must locate).
Finally, `ld-linux.so` writes the actual address of the `puts` procedure into the `puts` entry of the global-offset table, and, after unwinding the stack a bit, passes control to `puts`. On subsequent calls by the module to `puts`, since the global-offset table now contains `puts`'s address, control goes to it more directly, without an invocation of `ld-linux.so`.
Quiz 2

On the second and subsequent calls to *puts*

a) control goes directly to *puts*
b) control goes to an instruction that jumps to *puts*
c) control still goes to ld-linux.so, but it now transfers control directly to *puts*
