(pictures: Wikipedia)
Basic to problem solving:

• *How to take action to reach a goal?*
Search

Choices have consequences!
Search

Formalizing the problem statement …

• Problem can be in various states.
• Start in an initial state.
• Have some actions available.
• Each action has a cost.
• Want to reach some goal, minimizing cost.

Happens in simulation.
Not web search.
Formal Definition

Set of states $S$

Start state $s \in S$

Set of actions $A$ and action rules $a(s) \rightarrow s'$

Goal test $g(s) \rightarrow \{0, 1\}$

Cost function $C(s, a, s') \rightarrow \mathbb{R}^+$

So a search problem is specified by a tuple, $(S, s, A, g, C)$. 
Problem Statement

Find a sequence of actions $a_1, \ldots, a_n$ and corresponding states $s_1, \ldots, s_n$ ... such that:

- $s_0 = s$ start state
- $s_i = a_i(s_{i-1})$, $i = 1, \ldots, n$ legal moves
- $g(s_n) = 1$ end at the goal

while minimizing:

$$\sum_{i=1}^{n} C(s_{i-1}, a, s_i)$$ minimize sum of costs - rational agent

...
Example

Sudoku

States: all legal Sudoku boards.

Start state: a particular, partially filled-in, board.

Actions: inserting a valid number into the board.

Goal test: all cells filled and no collisions.

Cost function: 1 per move.
Example

**States:** airports, times.

**Start state:** TF Green, 5pm at the earliest.

**Actions:** available flights from each airport.

**Goal test:** reached Tokyo by midnight tomorrow.

**Cost function:** time and/or money.
The Search Tree

Classical conceptualization of search.
The Search Tree
Important Quantities

Branching factor (*breadth*)

![Branching factor diagram](image-url)
The Search Tree

Depth
- min solution depth $m$
- depth $d$

$O(b^d)$ leaves in a tree of breadth $b$, depth $d$.

$\sum_{i=0}^{d} b^i \in O(b^d)$ total nodes in the same tree
The Search Tree

Expand the tree one node at a time.
Frontier: set of nodes in tree, but not expanded.

Key to a search algorithm: which node to expand next?
visited = {}
frontier = {s_0}
goal_found = false

while not goal_found:
    node = frontier.next()
    frontier.del(node)

    if(g(node)):
        goal_found = true
    else:
        visited.add(node)
        for child in node.children:
            if(not visited.contains(child)):
                frontier.add(child)

expand tree!
How to Expand?

*Uninformed strategy:*

- nothing known about likely solutions in the tree.

What to do?

- Expand deepest node (*depth-first search*)
- Expand closest node (*breadth-first search*)

Properties

- Completeness
- Optimality
- Time Complexity (*total number of nodes visited*)
- Space Complexity (*size of frontier*)
Depth-First Search

Expand deepest node

\[ \text{s0} \rightarrow \text{s1} \]
Depth-First Search

Expand deepest node
Depth-First Search

Expand deepest node
Depth-First Search

Expand deepest node
Depth-First Search

Expand deepest node

\[
\begin{array}{c}
\text{s0} \\
\text{s1} \\
\text{s2} \\
X \\
\text{s3} \\
\text{s4}
\end{array}
\]
DFS: Time

\[ O(b^d - b^{d-m}) = O(b^d) \]

worst case: solution on this branch
DFS: Space

worst case: search reaches bottom

$b-1$ nodes open at each level

d levels

$O((b-1)d) = O(bd)$
Depth-First Search

Properties:
• Completeness: Only for finite trees.
• Optimality: No.
• Time Complexity: $O(b^d)$
• Space Complexity: $O(bd)$

Note that when reasoning about DFS, $m$ is depth of found solution (not necessarily min solution depth).

The deepest node happens to be the one you most recently visited - easy to implement recursively OR manage frontier using LIFO queue.
Breadth-First Search

Expand shallowest node

Diagram:
- Node s0
- Node s1
- Edge from s0 to s1
Breadth-First Search

Expand shallowest node
Breadth-First Search

Expand shallowest node
Breadth-First Search

Expand shallowest node
Breadth-First Search

Expand shallowest node
BFS: Time

\[ O(b^m) \]
BFS: Space

\[ O(b^{m+1}) \]
Breadth-First Search

Properties:
- Completeness: Yes.
- Optimality: Yes for constant cost.
- Time Complexity: $O(b^m)$
- Space Complexity: $O(b^{m+1})$

Manage frontier using FIFO queue.
Bidirectional Search
Iterative Deepening Search

DFS: great memory cost, but suboptimal solution.
BFS: optimal solution but horrible memory cost.

The core problems in DFS are a) not optimal, and b) not complete … because it fails to explore other branches.

Otherwise it’s a very nice algorithm!

Iterative Deepening:
• Run DFS to a fixed depth $z$.
• Start at $z=1$. If no solution, increment $z$ and rerun.
IDS

run DFS to this depth
IDS

How can that be a good idea?

*It duplicates work.*

Optimal for constant cost! *Proof?*

Also!

- Low memory requirement (equal to DFS).
- Not many more nodes expanded than BFS.
  (About twice as many for binary tree.)
IDS

visited $m + l$ times

visited $m$ times

...
IDS

\[ \sum_{i=0}^{m} b^i (m - i + 1) = \frac{b(b^{m+1} - m - 2) + m + 1}{(b - 1)^2} \]

# revisits

# nodes at level \( i \)

BFS worst case: \[ \frac{b^{m+1} - 1}{b - 1} \]
IDS

Key Insight:
• Many more nodes at depth $m+1$ than at depth $m$.

MAGIC.

“In general, iterative deepening search is the preferred uninformed search method when the state space is large and the depth of the solution is unknown.” (R&N)
Informed Search

What if we know something about the search?

How should we include that knowledge?  
In what form should it be expressed to be useful?
Uninformed Searches

Simple strategy for choosing next node:

- Choose the shallowest one (breadth-first)
- Choose the deepest one (depth-first)

Neither guaranteed to find the least-cost path.

What if we chose the one with lowest cost?
Uniform-Cost

Order the nodes in the frontier by **cost-so-far**
- Cost from the start state to that node.

Open the next node with the smallest cost-so-far
- Optimal solution
- Complete (provided no negative costs)
Uniform-Cost

Expand cheapest node
Use whole path cost

![Diagram showing nodes s0, s1, and s2 with edges and costs 5 and 11.](image)
Uniform-Cost

Expand cheapest node
Use *whole path* cost

Diagram showing a tree structure with nodes labeled as s0, s1, s2, s3, and s4, with edges labeled with costs (5, 11, 4, 7) respectively.
Uniform-Cost

Expand cheapest node
Use whole path cost
Uniform-Cost

Expand cheapest node
Use *whole path* cost
What Does This Suggest?

The *cost-so-far* tells us how much it cost to get to a node.
- Go to cheapest nodes first.

What remains?

**Total cost** = **cost-so-far** + **cost-to-go**

**Cost-so-far**: cost from start to node.
**Cost-to-go**: cost from node to goal.
Informed Search

Key idea: *heuristic function*.

- $h(s)$ - estimates cost-to-go
- Cost to go *from* state *to* solution.
- **Problem specific (hence *informed*)**
Greed

What if we expand the node with lowest $h(s)$?
Informed Search: A*

A* algorithm:

- $g(s)$ - cost so far (start to $s$).
- Expand $s$ that minimizes $g(s) + h(s)$ both
- Manage frontier as priority queue.

- Admissible heuristic: never overestimates cost.
  
  $h(s) \leq h^*(s)$

- $h(s) = 0$ if $s$ is a goal state, so $g(s) + h(s) = c(s)$

- If $h$ is admissible, A* finds optimal solution.
- If $h(s)$ is exact, runs in $O(bd)$ time.
Admissible Heuristics

Optimality:
Proof by contradiction
**Proof**

Assume:

\[ g(s_a) > g(s_{opt}) \]

But if \( s_a \) was opened before \( s_b \) then:

\[ g(s_a) + h(s_a) \leq g(s_b) + h(s_b) \]

But if \( h \) is admissible then:

\[ g(s_b) + h(s_b) \leq g(s_b) + h^*(s_b) = g(s_{opt}) \]

...but then:

\[ g(s_a) \leq g(s_b) + h(s_b) \leq g(s_{opt}) \]
Example Heuristic
More on Heuristics

Ideal heuristics:
• Fast to compute.
• Close to real costs.

Some programs *automatically generate* heuristics.
