

A Randomized Parallel Algorithm for Single-Source Shortest Paths*

Philip N. Klein and Sairam Subramanian

Department of Computer Science, Brown University, Providence, Rhode Island

Received August 22, 1991

We give a randomized parallel algorithm for computing single-source shortest paths in weighted digraphs. We show that the exact shortest-path problem can be efficiently reduced to solving a series of approximate shortest-path subproblems. Our algorithm for the approximate shortest-path problem is based on the technique used by Ullman and Yannakakis in a parallel algorithm for breadth-first search. © 1997 Academic Press

1. INTRODUCTION

One of the most fundamental and ubiquitous problem in combinatorial optimization is finding single-source shortest paths in a weighted graph. Aside from being important in its own right, the problem arises in algorithms for many other problems, especially those related to flow.

In view of the importance of the single-source shortest-path problem, it is unfortunate that previously known *parallel* algorithms for this problem are very inefficient on sparse graphs. This inability to make efficient use of parallelism in computing shortest paths is of both theoretical and practical significance. A fast and efficient parallel algorithm for this problem remains a major goal in the design of parallel graph algorithms.

In this paper, we describe a parallel randomized algorithm for computing single-source shortest paths. Our algorithm achieves a significant speed-up even when only a linear number of processors is available.

*Research support by NSF Grant CCR-9012357 and an NSF PYI award, together with PYI matching funds from Thinking Machines Corporation and Xerox Corporation. Additional support provided by ONR and DARPA Contract N00014-83-K-0146 and ARPA Order No. 6320, Amendment 1.

In the following bounds, we assume the concurrent-write PRAM as our model of parallel computation: multiple processors can simultaneously read and write to a shared memory. If multiple processors attempt to write multiple values to a single location, an arbitrary one succeeds.

In stating our results, we specify the time required and the number of processors. We also specify the *work* required by the algorithm. Here *work* is defined to be the product of time and number of processors required; this corresponds to the time that would be required if the parallel processors were all simulated by a single processor. Work is a measure that reflects how efficiently the processors are being used by a parallel algorithm; one can compare the work to the time required by a sequential algorithm for the same problem.

THEOREM 1.1. *Let c be any positive constant. There is a randomized parallel algorithm that, given a directed graph G with nonnegative integer lengths and given a source node s , computes shortest-path distances from s to all the other nodes in the graph with probability $1 - n^{-c}$. The algorithm takes $O(\sqrt{n} \log L \log n \log^* n)$ time using $O(m/\log^* n)$ processors, for a total of $O(m\sqrt{n} \log L \log n)$ work, where m , n , and L are, respectively, the number of edges in G , the number of nodes, and the sum of edge lengths.*

By comparing the work required by our algorithm to the $O(m + n \log n)$ time required by a sequential algorithm for shortest paths, we see that our algorithm occurs an $O(\sqrt{n} \log L \log n)$ factor overhead. Our algorithm is based on a parallel breadth-first search algorithm due to Ullman and Yannakakis [18].

Ullman and Yannakakis show that a breadth-first search tree can be constructed in $O(\sqrt{n} \text{polylog } n)$ time using a linear number of processors. Their algorithm is limited, however, in that it cannot handle lengths on nodes or edges. Thus our main contribution is to extend their algorithm so that it can do so. We first show that using a simple rounding technique enables their algorithm to approximate shortest paths in the presence of lengths. We then show how to use this approximation algorithm along with a scaling technique to get exact shortest paths. The scaling technique is similar to the one used by Gabow [8] for sequential computation of shortest paths.

In other related work, a parallel algorithm for shortest paths was discovered by Spencer [17]. Actually, his algorithm involves a tradeoff between time and work. Spencer specifies his bounds in terms of a parameter ρ and an upper bound L on edge lengths (assuming the lengths are positive integers). The time required is $O((n/\rho) \log n \log(\rho L))$ and the work is $O(n\rho^2 \log \rho \log(\rho L) + (m + n \log L)\text{polylog}(n))$. For comparison,

let us ignore logarithmic factors; to achieve about \sqrt{n} time, Spencer's algorithm would need to do about n^2 work, whereas our algorithm would need to do about $m\sqrt{n}$ work. Thus our algorithm is considerably more efficient in the case where the graph is sparse (i.e., m not much larger than n) and less efficient if the graph is dense (i.e., m larger than $n^{1.5}$). Put another way, if the graph is sparse ($m = O(n)$) and one only has n processors available, our algorithm would use the n processors to achieve a speed-up of about \sqrt{n} , while Spencer's algorithm would achieve a speedup of about $n^{1/4}$.

1.1. Subsequent Work

In recent work Cohen [5] has given an algorithm to find $(1 + \epsilon)$ -approximate shortest paths that works in polylogarithmic time and does close to linear work. Her algorithm makes use of the limited-search algorithm presented in this article. Thus for undirected graphs the work complexity of Cohen's [5] algorithm is close to optimal. However, her algorithm does not generalize to directed graphs; and there seems to be no way to use it to compute exact shortest paths by repeated approximation even if the underlying graph is undirected.

More recently, Shi and Spencer [16] have given a parallel shortest-path algorithm, for undirected graphs, with work bounds that are similar to ours. Given $\log n \leq t \leq n$, their algorithm runs in $\tilde{O}(t)$ time with $\tilde{O}((n^3/t^2) + m)$ work, or in $\tilde{O}(t)$ time with $\tilde{O}((n^3/t^3) + mn/t)$ work.

To compare the relative efficiency of the two algorithms, we set t to be \sqrt{n} . If we assume that the edge lengths are polynomially bounded, then for undirected graphs to the two algorithms require roughly the same amount of work. However, like Cohen's algorithm, their algorithm does not generalize to directed graphs either.

In other work [14] we have given a nearly work-optimal parallel algorithm for computing single-source shortest paths if the underlying graph is planar.

2. BACKGROUND AND OVERVIEW

A word about terminology in order to forestall confusion. Unless otherwise stated, when we speak of the *length* of a path, we mean the sum of the lengths of its edges (rather than the number of its edges). Similarly, *distance* is measured according to edge lengths. The *size* of a path, on the other hand, shall signify the number of edges in the path, and the *minimum path size* is the shortest distance measured in the number of edges traversed.

Unless otherwise stated, n and m denoted, respectively the number of nodes and the number of edges in the input graph.

2.1. *Parallel Breadth-First Search*

The fastest known parallel algorithm for breadth-first search involves repeatedly squaring a matrix, where the elementwise operations are in the min-plus semiring. In fact, this algorithm can compute shortest paths. The technique is well known; see [1, 7] for more details. The problem with this algorithm is that it requires too many processors; to achieve $O(\log n)$ time requires about n^3 processors. The processor bound has been improved somewhat [9] in the case of breadth-first search.

The most elementary parallel search technique is parallel breadth-first search, in which the nodes are visited level by level as the search progresses. Level 0 consists of the starting node s , level 1 consists of the neighbors of s , level 2 consists of the neighbors of the neighbors of s (or, rather, those not belonging to previous levels), and so forth.

2.2. *Limited Breadth-First Search*

The problem with this approach is that the time required grows linearly with the number of levels traversed. To keep the time small, we must resort to a limited search, in which we limit the number of levels traversed. For a parameter k , a search that visits k levels beyond the source is called a *k-limited breadth-first search*. Note that such a search determines the distance from the source to each node at distance at most k . This kind of search is used in the algorithm of Ullman and Yannakakis.

Suppose there are p processors, to go from level $i + 1$, the processors first divide up the edges outgoing from the level i nodes. This step can be done with high probability in $O(\log^* p)$ time using the parallel load-balancing algorithm of [10]. Next, for each such edge, if the other endpoint has not yet been traversed, it is assigned to level $i + 1$. This step can be done in $O(m_i/p)$ time, where m_i is the number of such edges. Hence the time required to traverse k levels is $O(m/p + k \log^* p)$ with high probability.

2.3. *Ullman and Yannakakis's Algorithm*

We now give a brief description of the basic version of Ullman and Yannakakis's parallel algorithm for breadth-first search. We describe our adaptation of their algorithm in greater detail in Section 4.1.

The algorithm is based on $\sqrt{n} \log n$ -limited search. We are given a graph and a source s from which to find a breadth-first search tree. First, $O(\sqrt{n})$ randomly chosen nodes, along with the source, are designated as *distin-*

guished. (The constant hidden by the O determines the probability that the algorithm is correct, as we mention below.) From each of the distinguished nodes x in parallel, p processors conduct a $\sqrt{n} \log n$ -limited search, identifying the minimum path size from x to each node within path size \sqrt{n} . By choosing p to be m/\sqrt{n} , we can carry out all of these searches in $O(\sqrt{n} \log n \log^* n)$ time using a total of $p\sqrt{n} = m$ processors.

Second, an auxiliary graph is formed on the set of distinguished nodes, where the length of an edge from u to v is defined to be the minimum path size from u of v found during the limited search. All-pairs shortest paths are computed for the auxiliary graph. This takes total work $O((\sqrt{n})^3 \log n)$, and can easily be done in $O(\sqrt{n} \log n)$ time using m processors. In particular, we have the length of the shortest path in the auxiliary graph from the source s to each of the distinguished nodes.

Third, the minimum path size from the source s to a node v is computed by taking the minimum, over all distinguished nodes x , of the auxiliary-graph shortest path length from s to x plus the minimum path size from x to v found in x 's limited search. One can show that, with high probability, this method yields the minimum path size for all nodes v .

The proof is as follows. Fix in advance one minimum-size path P_v from s to v for every node v . Now consider the randomly selected distinguished nodes. With probability $1 - 1/n^c$ (where c is any given constant, and determines the constant factor in the number of randomly chosen nodes), for each node v each subpath of P_v of size $\sqrt{n} \log n$ contains a distinguished node.

Thus the path P_v is broken up into subpaths starting and ending with distinguished nodes (except for the last subpath, which ends on v), such that each subpath has size at most $\sqrt{n} \log n$. These subpaths are traversed in the limited search. Hence the minimum path size from s to the last distinguished node of P_v is correctly computed in the all-pairs computation, and the minimum path size from s to v is correctly computed in the last step of the algorithm.

3. APPROXIMATELY SHORTEST PATHS

Ullman and Yannakakis's approach does not directly work with weighted graphs because there is no apparent way to find even the $\sqrt{n} \log n$ -limited shortest paths within the available resource bounds. Our first contribution is a method that approximates these shortest paths. We start with some definitions.

For a parameter k , a k -limited shortest path from s to t is a path from s to t that is no longer than any s -to- t path of size at most k . Note that a

k -limited shortest path need not itself have size at most k . For any given error parameter $\epsilon > 0$, we define a k -limited ϵ -approximate shortest path to be one whose length is at most $1 + \epsilon$ times the length of any path of size at most k . We show how to search such paths in parallel in $O(k\epsilon^{-1})$ iterations, loosely speaking.

To be more precise, we say that an estimate d of the distance from s to t is a k -limited ϵ -approximate shortest-path distance if there is an s -to- t path of length at most d , and d is at most $1 - \epsilon$ times the length of any path of size at most k .

We provide a procedure that, given a source node and a parameter k , finds such k -limited ϵ -approximate distances from the source of all nodes. If the edge lengths are polynomial in magnitude, the procedure runs in time

$$O\left(\frac{m \log n}{p} + k\epsilon^{-1} \log^* p\right)$$

using p processors.

By substituting $k = \sqrt{n} \log n$ and $p = O(m\epsilon / \sqrt{n} \log^* n)$ and running $O(\sqrt{n})$ instances of the procedure in parallel, we can implement an approximate version of Ullman and Yannakakis' first step in $O(\sqrt{n} \log n \epsilon^{-1} \log^* p)$ time using $O(m\epsilon / \log^* n)$ processors. Note that this procedure is sufficient to make Ullman and Yannakakis's procedure work for finding approximate single-source shortest paths in weighted graphs; the second and third steps do not depend on the lengths being one. By applying essentially the same proof as sketched previously for Ullman and Yannakakis' algorithm, one can show that the resulting single-source distances are within a factor of $1 + \epsilon$ of the true distances. An earlier version of this paper [13] used this limited-search idea to compute approximate single-source shortest paths.

Our second contribution is a reduction technique (derived from one due to Gabow [8]) that allows us to solve the exact problem by solving a series of approximate problems. In Section 4 we show how to use this approximation algorithm to find exact single-source shortest paths.

3.1. Parallel Dijkstra Search

There is an obvious approach to extending parallel breadth-first search to handle positive integral weights: imitate Dijkstra's algorithm. To handle level i , the processors first divide up the outgoing edges as before. Then, for each such edge uv , the level of v is assigned to be i plus the length of uv (if this value is less than the level previously assigned to v). Thus level i consists of those nodes at distance i from the source. The algorithm processes the nodes at level 0, then level 1, then level 2, and so on. For our purposes, it is not necessary to skip empty levels.

This process requires maintenance of the set of nodes in each level and load balancing within an iteration. The methods of Gil, Matias, and Vishkin [10] suffice to implement each iteration randomly in $O(\log^*n)$ time with high probability. Thus the time required to traverse k level is $O(m/p + k \log^*p)$ using p processors.

3.2. Approximating k -Limited Shortest-Path Distances

Parallel Dijkstra search is useful when (1) one need not search nodes far from the source and (2) all lengths are positive integers. However, one would like to be able to find the k -limited distance of nodes far from the source and to handle zero lengths. We show that this is possible if one is willing to accept approximate distances.

The first trick is to do a logarithmic number of independent searches in parallel. The first search is responsible for estimating very small distances, the second is responsible for estimating slightly larger distances, and so on. Each of these searches works with a different *granularity* α . Edge lengths are rounded up to the nearest multiple of α . In the corresponding parallel Dijkstra search, level i corresponds to distance $i\alpha$ from the source. A search responsible for estimating large distances can use a large value of α ; this ensures that only few levels need be traversed in order to reach large distances. The disadvantage of a large value of α is that the rounding is less accurate; however, the estimates obtained are for longer distances, so the percentage error is no greater.

Rounding up to the nearest α introduces an absolute error of at most α in each edge. Thus paths with many edges accumulate lots of error. Because we are interested in k -limited distances, we can control the accumulation of this error.

We also need a way of handling zero-length edges. First, we can use ordinary k -limited search on the subgraph of zero-length edges in order to find all nodes whose k -limited distance from the root source is zero. Second, for each of the logarithmic independent searches described previously, we round zero lengths up to the granularity α . This introduces some error but as before the total error is limited.

3.3. The Procedure FULLSEARCH

In this section we give the procedure FULLSEARCH for finding approximate k -limited shortest paths from a given source node s . It makes use of a subprocedure SEARCH(G, s, d, k, p, ϵ) that determines the k -limited ϵ -approximate shortest-path distances from s of those nodes whose distance is at least d and at most $2d$.

The procedure FULLSEARCH finds k -limited approximate shortest-path distances of all nodes simply by calling SEARCH(G, s, d, k, p, ϵ) in parallel

with $d = 1, 2, 4, \dots$. Let L be the sum of the edge lengths. Since no node is at distance more than L from the source, we need to consider only $\lceil \log L \rceil$ different values for d in order to determine approximate k -limited shortest paths to all the nodes. Thus FULLSEARCH makes $\log L$ parallel calls to SEARCH, each with d assigned a different power of 2 from 2^0 to $2^{\lceil \log L \rceil - 1}$. Then, for each node, we take its estimated distance to be the minimum estimated distance obtained. Later, in Lemma 3.2, we show that the distances thereby obtained are good estimates.

Now we outline the subprocedure SEARCH(G, s, d, k, p, ϵ). The first step of the subprocedure is to define the *scale factor* α by

$$\alpha = \epsilon d / k. \quad (1)$$

Next we obtain approximate edge lengths by rounding each length up to the nearest integer multiple of α . Zero lengths are rounded up to α .

$$\hat{l}(e) = \begin{cases} \alpha \lceil l(e) / \alpha \rceil & \text{if } l(e) > 0, \\ \alpha & \text{if } l(e) = 0. \end{cases}$$

Since the resulting lengths are positive integer multiples of α , we can apply parallel Dijkstra search where, in each level, we traverse a distance α . Search, from the source for $\lceil 2(1 + \epsilon)k / \epsilon \rceil$ levels, and label each node reached with the estimated distance, that is, α times the number of levels the search required to reach the node. The estimated distance to a node not reached by the search is implicitly taken to be infinite.

The time required to traverse $\lceil 2(1 + \epsilon)k / \epsilon \rceil$ levels is $O(m/p + 2k\epsilon^{-1} \log^* p)$ with high probability using p processors.

Next we show that the estimated distances computed are not too bad. The following proposition follows immediately from the fact that the approximate edge lengths are at least the actual edge lengths.

PROPOSITION 3.1. *For any path P , $\hat{l}(P) \geq l(P)$.*

Proposition 3.1 ensures that we never underestimate distances. We might overestimate distances, but lengths of paths with at most k edges and distance at least d are not overestimated by much.

LEMMA 3.1. *Suppose P is a source-to- v path of size at most k and length between d and $2d$. The estimated distance to v is at most $1 + \epsilon$ times the length of P .*

Proof. For each edge e of P , $\hat{l}(e) \leq l(e) + \alpha$, so $\hat{l}(P) \leq l(P) + k\alpha$. By the choice of α , we have $k\alpha = \epsilon d$. Since $l(P)$ is at least d , we obtain $\hat{l}(P) \leq (1 + \epsilon) l(P)$. Furthermore, since $l(P) \leq 2d$, we have $\hat{l}(P) \leq 2(1 + \epsilon)d$, so $\lceil 2(1 + \epsilon)k / \epsilon \rceil$ levels are sufficient to traverse P . Hence the estimated distance to v is at most $\hat{l}(P)$. ■

Next we show that FULLSEARCH assigns accurate distance estimates. Recall that the distance FULLSEARCH assigns to a node v is the minimum of all estimated distances to v obtained by the calls to the subprocedure SEARCH.

LEMMA 3.2. *The procedure FULLSEARCH computes k -limited ϵ -approximate shortest-path distances in time.*

Proof. For any node v , the estimated distance to v is at least the actual distance, by Proposition 3.1. Suppose v is at distance $d(v)$ from the source. Let $d_0 = 2^{\lceil \log d(v) \rceil}$, so $d_0 \leq d(v) \leq 2d_0$. Then, the Lemma 3.1, when SEARCH is called with $d = d_0$, the estimated distance to v is at most $(1 + \epsilon)$ times the length of any path to v with k edges. ■

The time required by FULLSEARCH is dominated by the time for the parallel calls to SEARCH. With p processors, the time required is thus

$$O\left(\frac{m \log L}{p} + k \epsilon^{-1} \log^* p\right). \quad (2)$$

In the next section, we show how to use a series of calls to FULLSEARCH in order to determine exact distances. Each such call involves edge lengths that are bounded by $2n$. Hence the factor $\log L$ in (2) is, in fact, $O(\log n)$ in this application.

4. COMPUTING EXACT SHORTEST PATHS BY REPEATED APPROXIMATION

In this section we show how to use the procedure FULLSEARCH to compute exact shortest paths in a directed graph G .

Gabow [8] has given a scaling algorithm to compute single-source shortest paths in a graph with maximum edge length L by solving a series of $\log L$ subinstances (involving the same graph with different edge lengths) in which each shortest-path distance is guaranteed to be at most n , the number of nodes. For such an instance, any edge whose length exceeds n is superfluous and can be discarded. We slightly generalize his reduction to allow for approximate solution of the subinstances.

The central idea of Gabow's scaling algorithm is modifying edge lengths according to node *prices* derived from a previous shortest-path calculation. For intuition, think of an edge's length as the cost one must pay to traverse that edge. Suppose that, for each node v , we have a *price* $p(v)$. Think of the price of v as the reward for entering the node and the cost of leaving

it. When one takes into account the prices, the *net cost* $\ell_p(uw)$ of traversing an edge uw is

$$\ell_p(uw) = \ell(uw) + p(u) - p(v).$$

The net cost of traversing a path depends on the prices of the starting and ending nodes, not on the prices of intermediate nodes, because the path both enters and leaves each intermediate node. In particular, for a path P from x to v ,

$$\ell_p(P) = p(x) + \ell(P) - p(v). \quad (3)$$

For any two nodes x and v , therefore, an x -to- v path is shortest with respect to the original edge costs if and only if it is shortest with respect to the net costs. Thus introduction of prices yields an equivalent shortest-path problem.

Prices are useful because they can reduce the costs of the edges in shortest paths. Suppose, for example, that the price of each node v is the length of the shortest path from the source to v . Let P be this shortest path. By substituting 0 for $p(\text{source})$ and $\ell(P)$ for $p(v)$ in Eq. (3), we see that the net cost of the shortest source-to- v path is zero.

In solving a shortest-path problem, we cannot assign exact shortest-path distances as prices because we do not know those distances. However, given a subroutine for estimating shortest-path distances, we can use these estimates as prices. With respect to the resulting net costs, the shortest-path distances are smaller than before. This is the idea at the core of Gabow's scaling algorithm. To obtain estimates, he replaces the edge lengths with approximations of them and computes exact shortest-path distances with respect to these approximate lengths. In our case, exact shortest-path distances are not available; however, we show that it is sufficient to calculate estimates of the shortest-path distances with respect to the approximate lengths.

In assigning prices, however, we must ensure that the resulting net costs remain nonnegative. We therefore require that the distance estimates are underestimates and, in particular, that they are exact shortest-path distances with respect to smaller costs. These considerations lead us to the following definition.

We define the $(1 - \epsilon)$ -approximate shortest-path problem to be computing distance estimates $d(v)$ in a graph G from given source such that:

(A) There is an auxiliary graph H whose node set is a subset of G 's node set such that the estimates are exact shortest-path distances in $G \cup H$.

(B) If the distance in the original graph from one node to another is d , the distance in $G \cup H$ is between $(1 - \epsilon)d$ and d .

Thus in the $(1 - \epsilon)$ -approximate problem we are interested in getting underestimates instead of overestimates. We now prove that the single-source shortest-path problem is efficiently polylog-time-reducible to the $(1 - \frac{1}{2})$ -approximate shortest-path problem. In Section 4.1, we show how to obtain such underestimates using the procedure FULLSEARCH.

LEMMA 4.1. *Single-source directed shortest paths in an n -node graph with nonnegative integral lengths and maximum shortest-path length D can be solved using $O(\log D)$ calls to an algorithm for computing $\frac{1}{2}$ -approximate shortest paths in the same graph (but with edge lengths less than $2n$).*

Proof. We give a recursive algorithm (essentially a reformulation of Gabow's algorithm) and show it has recursion depth at most $\log_{4/3} D$.

Let G be the input graph, and let $\lambda(e)$ be an assignment of lengths to edges. Let D be an upper bound on the distance of the farthest node from the source. Let $\delta := \lceil \log(D + 1) \rceil - \lceil \log n \rceil - 1$.

The algorithm first discards any edges with length more than D . The algorithm then assigns each edge e an approximate length $\hat{\lambda}(e) := \lfloor \lambda(e)/2^\delta \rfloor$. That is, $\hat{\lambda}(e)$ consists of the bits of $\lambda(e)$ in positions

$$\lceil \log(D + 1) \rceil - 1, \lceil \log(D + 1) \rceil - 2, \dots, \delta - 1.$$

Thus each approximate length consists of $\lceil \log n \rceil$ bits.

Next the algorithm computes single-source distance estimates $\hat{d}(v)$ with respect to the lengths $\hat{\lambda}(e)$. The estimates obey properties (A) and (B) in the definition of the $(1 - \epsilon)$ -approximate shortest-path problem. If the estimates are all zero, then by property (B) the exact distances are all zero. Otherwise the algorithm defines edge lengths $\lambda'(uw)$ by

$$\lambda'(uw) := \lambda(uw) + \lfloor 2^\delta \hat{d}(u) \rfloor - \lfloor 2^\delta \hat{d}(v) \rfloor.$$

Let $D' := \lfloor \frac{3}{4} D \rfloor$. We show later that D' is an upper bound on the distance of the farthest node from the source with respect to the lengths $\lambda'(e)$. The algorithm then recursively computes exact shortest-path distances $d'(v)$ with respect to these lengths.

Finally, the algorithm computes exact shortest-path distances $d(x)$ in the original graph by setting

$$d(x) := d'(x) + \lfloor 2^\delta \hat{d}(x) \rfloor.$$

The correctness of this procedure is proved as follows. For any node x and any path P from the source to x ,

$$\begin{aligned} \prime(P) &= \sum_{uw \in P} \left[2^\delta \hat{d}(u) \right] + \prime(uw) - \left[2^\delta \hat{d}(v) \right] \\ &= \left[2^\delta \hat{d}(\text{source}) \right] + \prime(P) - \left[2^\delta \hat{d}(x) \right] \\ &= 0 + \prime(P) - \left[2^\delta \hat{d}(x) \right]. \end{aligned} \quad (4)$$

It follows that the shortest source-to- x path P with respect to the original lengths $\prime(e)$ corresponds to the shortest path with respect to the lengths $\prime'(e)$. Moreover, the distance to x with respect to the lengths $\prime(e)$ is just $\left[2^\delta \hat{d}(x) \right]$ plus the distance with respect to the length $\prime'(e)$. Thus the distances in the original graph are computed correctly.

Next we show that the new lengths $\prime'(e)$ are nonnegative. This property derives from property (A) of the approximation. Let \hat{G} denote the graph with edge lengths $\hat{\lambda}(e)$. Let H be the auxiliary graph of property (A). For any edge uw , the u -to- v distance in $\hat{G} \cup H$ is clearly at most $\hat{\lambda}(uw)$, so the distance estimates $\hat{d}(x)$ obey

$$\hat{d}(v) \leq \hat{d}(u) + \hat{\lambda}(uw).$$

It follows that $\left[2^\delta \hat{d}(v) \right] \leq \left[2^\delta \hat{d}(u) \right] + \prime(uw)$, so $\prime'(uw) \geq 0$.

Finally, we show that $D' = \left\lfloor \frac{3}{4} D \right\rfloor$ is an upper bound on the distance of the farthest node from the source with respect to the new lengths $\prime'(e)$. Note that this shows the recursion depth is at most $\log_{4/3} D$.

For any node x , let P be a shortest path to x with respect to lengths $\prime'(uw)$:

$$\begin{aligned} \prime'(P) &= \sum_{e \in P} \left\lfloor \prime'(e) / 2^\delta \right\rfloor \\ &\geq \sum_{e \in P} \left(\prime'(e) / 2^\delta - 1 \right) \\ &\geq \prime'(P) / 2^\delta - n. \end{aligned}$$

By property (B) of the distance estimates,

$$\begin{aligned} \hat{d}(x) &\geq \left(1 - \frac{1}{2} \right) \prime'(P) \\ &\geq \frac{1}{2} \prime'(P) / 2^\delta - n/2. \end{aligned}$$

Finally, using (4), we obtain

$$\begin{aligned} \prime(P) &= \prime'(P) - \left[2^\delta \hat{d}(x) \right] \\ &\leq \prime'(P) - \frac{1}{2} \prime'(P) + 2^\delta n/2 \\ &\leq \frac{1}{2} \prime'(P) + D/4. \end{aligned}$$

Thus the farthest node from the source is at a distance at most $D/2 + D/4$ with respect to lengths $l'(e)$. ■

4.1. Using the Procedure FULLSEARCH to Solve the $(1 - 1/2)$ -Approximate Shortest-Path Problem

We now show how our approximation algorithm can be used to get underestimates that satisfy properties (A) and (B). We closely follow the outline of the algorithm of Ullman and Yannakakis. Let G be the input graph, and let n and m denote, respectively, the number of nodes and number of edges in G . The first two steps are as follows. Randomly select $(c + 3)\sqrt{n}$ distinguished nodes, where c is a constant. Include the source node among the distinguished nodes. Use FULLSEARCH to find $(1 + \epsilon)$ -approximate $\sqrt{n} \log n$ -limited shortest paths from each distinguished node, where $\epsilon = 1/2$. The following lemma is the key idea in the algorithm of Ullman and Yannakakis.

LEMMA 4.2 (Ullman and Yannakakis). *With probability at least $1 - n^{-c}$, for every pair u, v of nodes of G there is a shortest u -to- v path such that every subpath of size $\sqrt{n} \log n$ contains a distinguished node.*

Next, construct a graph H whose nodes are the distinguished nodes and where there is an edge uv of length $(1 + \epsilon)^{-1}d$ if the estimates u -to- v distance is d . Use matrix powering to compute all-pairs shortest paths in H , and let H^* be the complete graph in which the length of the edge uv is the u -to- v distance in H .

We now show that distances in the union of H^* with the input graph G satisfy property (B).

LEMMA 4.3. *For every pair u, v of nodes of G , if the u -to- v distance in G is d , the u -to- v distance in $H^* \cup G$ is between $(1 - \epsilon)d$ and d .*

Proof. Since every path in G is a path in $H^* \cup G$, the u -to- v distance in $H^* \cup G$ is no more than the corresponding distance in G . Conversely, let P be a shortest u -to- v path in $H^* \cup G$. We must show that there is a corresponding path P'' in G whose length is not much more than that of P .

First, obtain P' from P by replacing each edge of H^* with the corresponding shortest path in H . Since the length of each edge of H^* equals the length of the corresponding shortest path in H , the length of P' equals the length of P .

Next, obtain P'' from P' by replacing each edge xy of H with the shortest x -to- y path P_{xy} of G . For each edge xy of H ,

$$\begin{aligned} \text{length}(xy) &= (1 + \epsilon)^{-1} \cdot \text{estimated } x\text{-to-}y \text{ distance in } G \\ &\geq (1 + \epsilon)^{-1} \cdot \text{actual } x\text{-to-}y \text{ distance in } G. \end{aligned}$$

Since we replace each such edge xy with a pair of length at most $1 + \epsilon$ times the length of xy , the resulting path P'' has length at most $1 + \epsilon$ times the length of the shortest u -to- v path P in $H^* \cup G$. Let d be the u -to- v distance in G . We have shown that d is at most $1 + \epsilon$ times the u -to- v distance in $H^* \cup G$; equivalently, the u -to- v distance in $H^* \cup G$ is at least $(1 + \epsilon)^{-1}d$, which in turn is at least $(1 - \epsilon)d$. ■

Finally, we obtain single-source distances in $H^* \cup G$. To do this, we rely on the following lemma.

LEMMA 4.4. *With probability at least $1 - n^{-c}$, for any node v , there is a shortest source-to- v path in $H^* \cup G$ that consists of at most $1 + \sqrt{n} \log n$ edges.*

Proof. Assume the high-probability event of Lemma 4.2 occurs, and let P be a shortest source-to- v path in $H^* \cup G$. Obtain P' from P as follows: for each maximal subpath P_i and P consisting solely of edges of G , replace P_i by the shortest path with the same endpoints whose existence is promised by Lemma 4.2. The resulting path P' has the following structure. It consists of the subpaths in G of size at most $\sqrt{n} \log n$ starting and ending at distinguished nodes, interspersed with edges of H^* , and ending with a subpath in G of size at most $\sqrt{n} \log n$. Furthermore, since P' was obtained by replacing shortest paths in G with shortest paths in G , the length of P' equals the length of P .

Obtain P'' from P' as follows. For each subpath P_i in G of size at most $\sqrt{n} \log n$ starting and ending at distinguished nodes, replace P_i with the edge e_i of H with the same endpoints. Suppose P_i is a u -to- v path, and note that since the estimated u -to- v distance is at most $1 + \epsilon$ times the length of P_i and the length of e_i is defined to be $(1 + \epsilon)^{-1}$ times the estimated distance, the length of e_i is at most the length of P_i . Hence the length of P'' is no more than the length of P' .

The structure of P'' is as follows. It consists of a subpath of edges of $H^* \cup H$, terminating in a subpath of G of size at most $\sqrt{n} \log n$. Obtain P''' from P'' by replacing the subpath of edges of $H^* \cup H$ by the single edge with the same endpoints. It follows that the length of P''' is no more than the length of P'' and P''' consists of at most $1 + \sqrt{n} \log n$ edges. ■

Lemma 4.4 shows that to compute single-source distances in $H^* \cup G$, it is sufficient to consider paths of size at most $k = 1 + \sqrt{n} \log n$. Cohen [3] has observed that the following variant of Bellman–Ford correctly computes shortest paths in the case. Set $d(v) := \infty$ for each node v , except set $d(\text{source}) := 0$. Repeat the following step k times. For each node v other than the source, compute

$$d(v) := \min\{d(u) + \text{length}(uv) : uv \text{ an incoming edge of } v\}.$$

Now we analyze the preceding algorithm. Carrying out FULLSEARCH for each distinguished node takes $O(\epsilon^{-1}\sqrt{n} \log n \log^*n)$ time and $O(m\sqrt{n} \log L)$ work. Since $L \leq n^3$, the work bound is $O(m\sqrt{n} \log n)$. Constructing the graph H can be done within the same bounds. Since H has $O(\sqrt{n})$ nodes, computing all-pairs shortest paths in H can be done in $O(\sqrt{n} \log n)$ time and $O(n^{1.5} \log n)$ work. Finally, using the Bellman–Ford variant to compute single-source shortest paths requires $O(\sqrt{n} \log n)$ stages (as noted previously). Each state can be implemented in constant time with high probability by using Megiddo's [15] algorithm for computing minimum. Therefore, the shortest paths in $H^* \cup G$ can be found in $O(\sqrt{n} \log n \log^*n)$ time and $O(m\sqrt{n} \log n)$ work. We therefore get the bounds of Theorem 1.1.

5. CONCLUSION

In this paper, we have given an answer to one of the open problems posed by Ullman and Yannakakis: "Does any of this material generalized to the general shortest-path problem, where arcs initially have arbitrary weight?" In particular, we have addressed the case of nonnegative integral weights whose magnitudes are not too large. A more ambitious goal, articulated by Ullman and Yannakakis, is a fast algorithm that works for an arbitrary closed semiring (see [1]). This remains a tantalizing open problem.
